Abstract

Climate change is considered as one of the main challenges to the urban wastewater systems during the next decades and it is estimated that has a dual action on wastewater treatment plants (WWTs). The processes occurring in a WWTP are subsequently affected by climate change; more extreme weather events and earlier snowmelt runoff will lead to more untreated sewer overflows, increased flooding, etc. On the other hand, we have the WWT contribution to climate change itself, as during the wastewater treatment, greenhouse gases (GHG) including carbon dioxide (CO₂) from aerobic (oxidation processes), methane (CH₄) from anaerobic processes and nitrous oxide (N₂O) associated with nitrification/denitrification (NDN) processes, can be emitted to the atmosphere. Membrane Biological Reactors (MBR) represents a rather innovative wastewater treatment system and the major GHG emissions are sourced from the anoxic/aerobic zones; however, it could be assumed that N₂O and CH₄ emissions would not be significant, as the system remains aerobic. Moreover, the microbial communities developed in MBRs are exposed to completely different conditions depending on the season of the year (spring, summer and autumn). The various problems associated with climate change and MBRs/WWT operation and the solutions that can be applied to deal with them, will be summarized in this paper.

Keywords

Climate change, wastewater treatment, MBRs.

1.1 Introduction

1.1.1 Wastewater Treatment Plants (WWTPs)

Each particular wastewater treatment plant (WTTP) may be subjected to various operation conditions and restrictions i.e. variable flow of incoming wastewater, quality of sewage, permitted levels of effluent and other local guidelines. These differences may have a significant impact on the type of process used for treatment.

A conventional municipal wastewater treatment plant includes the following main stages of processing:

i. Pretreatment: solids removal with relatively large diameters (e.g. > 1 mm);
ii. Primary treatment: removal of solids that settle relatively easily aiming to reduce the concentration of particulates;
iii. Secondary treatment: removal of biodegradable organic substances by biological processes (microorganisms consume the organic content under aerobic or anaerobic conditions);
iv. Tertiary Treatment and Disinfection: Removal of residual solids and nutrients (N, P) and destruction of pathogens microorganisms;
v. Sludge disposal: in landfills, by composting or by incineration [1].

![Figure 1: Conceptual diagram of a typical activated sludge process](image)

In the conventional municipal systems, wastewater after primary treatment, i.e. after suspended solids removal, is treated by the activated sludge process (Figure 1) consisted in an aeration tank followed by a
secondary clarifier. Nevertheless, activated sludge is the most common and oldest biological process used for the treatment of municipal and industrial wastewater.

### 1.1.2 Membrane Bioreactor Systems (MBRs)

Membrane bioreactors (MBRs) are becoming more common as WWTPs are required to meet increasingly stringent effluent limits and in some cases, reuse requirements in smaller footprints. The unique feature of MBRs is that instead of secondary clarification (Figure 2), they use membrane treatment, either as vacuum-driven systems immersed in a biological reactor or pressure-driven membrane systems located external to the bioreactor, for solids separation. Membranes are typically configured hollow tube fibers or flat panels and have pore sizes ranging from 0.1 to 0.4 microns. The membrane biological reactor configuration has proven to be optimal for the treatment of a large number of industrial wastewaters, especially when treatment efficiency is an important consideration [2].

![Conceptual diagram of a Membrane Bioreactor System](image)

**Figure 2: Conceptual diagram of a Membrane Bioreactor System [3].**

### 1.1.3 Climate Events

Climate change is one of the main challenges to the urban wastewater systems in the next decades. Due to increasing concentrations of greenhouse gases in our atmosphere, temperatures are expected to rise between 2 and 5 °C Celsius globally by 2050.

Climate change is affecting the hydrologic cycle in various ways. Precipitation patterns are changing, snow and ice is melting, and atmospheric water vapor and evaporation is increasing. Evaporation increases because of surface heating and with increased temperature the water-holding capacity of the atmosphere increases. As atmospheric moisture content directly affects precipitation, stronger rainfall events are expected with climate change [4].

The wastewater industry is beginning to address the challenges posed by climate change, including regulatory burdens, pressure to reduce emissions and the challenge of adapting to a changing climate [5].

### 1.1.4 Greenhouse Gases (GHG)

Gases that trap heat in the atmosphere are called greenhouse gases. CO₂ is the principal greenhouse gas (Figure 3), but other gases can have the same heat-trapping effect. Some of these other greenhouse gases, however, have a much stronger greenhouse, or heat-trapping, effect than CO₂. For example, methane is 21 times more potent a greenhouse gas than CO₂.

![Total Emissions in 2011](image)

**Figure 3: Total Emissions in 2011 = 6.702 Million Metric Tons of CO₂ equivalent [6].**
Different GHGs have different atmospheric life times, and therefore actions to reduce emissions will take time to effect reductions of gases in the atmosphere. The principal, human-generated greenhouse gases that enter the atmosphere are summarized in the below Table 1.

Table 1: The human-generated greenhouse gases that enter the atmosphere [6].

<table>
<thead>
<tr>
<th>GHGs</th>
<th>Characteristics</th>
</tr>
</thead>
<tbody>
<tr>
<td>Carbon Dioxide (CO₂)</td>
<td>Enters the atmosphere through the burning of fossil fuels (oil, natural gas and coal), production and transport of coal, natural gas and oil.</td>
</tr>
<tr>
<td>Methane (CH₄)</td>
<td>Results from livestock and other agricultural practices and by the decay of organic waste in municipal solid waste landfills and anaerobic wastewater treatment plants. CH₄ is a greenhouse gas approximately 21 times more potent than CO₂ and has an atmospheric lifespan of roughly 12 years.</td>
</tr>
<tr>
<td>Nitrous Oxide (N₂O)</td>
<td>Is emitted during agricultural and industrial activities, as well as during the combustion of fossil fuels and solid waste. Nitrous oxide is also emitted from wastewater treatment plants during nitrification and denitrification processes (NDN). N₂O is 310 times more potent as a greenhouse gas than CO₂ and has an atmospheric lifespan of 120 years.</td>
</tr>
<tr>
<td>Fluorinated Gases</td>
<td>Hydrofluorocarbons (HFCs), perfluorocarbons (PFCs) and sulfur hexafluoride (SF₆) are synthetic, powerful greenhouse gases that are emitted from a variety of industrial processes. These gases are typically emitted in smaller quantities, but because they are potent greenhouse gases, they are sometimes referred to as High Global Warming Potential gases (High GWP gases). HFCs are 140 to 11,700 times more potent than CO₂ and have atmospheric life spans of 1–260 years. Most commercially used HFCs remain in the atmosphere less than 15 years. PFCs are 6,500 to 9,200 times more potent than CO₂ and have an atmospheric lifespan of several thousand years. Sulfur hexafluoride is 23,900 times a more potent greenhouse gas than CO₂ and is extremely long lived with very few sinks.</td>
</tr>

</table>

1.2 WWT affected by Climate Change

1.2.1 Associated Problems

1.2.1.1 Climate Events

On a consideration of the wastewater infrastructure and baseline climate data, the following climate factors were identified as being particularly significant [7]:

- rainfall (intensity-frequency relationships, annual and seasonal totals). Wastewater infrastructure is affected by rainfall storm events and, to a lesser degree, by the total annual rainfall;
- sea level elevation;
- storm surge;
- rain on snow events (another flood generation mechanism);
- extreme temperaturs (low and high);
- drought conditions;
- snowfall (predicted increasing temperaturs in the next years in all months, estimate that snowfall is expected to decrease);
- wind speed (extremes and gusts);
- frost (freeze-thaw cycles); and
- ice.

Temperature
Biological wastewater treatment is very much influenced by climate. Temperature plays a decisive role in some treatment processes, especially the natural-based and non-mechanized ones. Warm temperatures decrease land requirements, enhance conversion processes, increase removal efficiencies and make the utilization of some treatment processes feasible. Some treatment processes, such as anaerobic reactors, may be utilized for diluted wastewater, such as domestic sewage, only in warm climate areas. Other processes, such as stabilization ponds, may be applied in lower temperature regions, but occupying much larger areas and being subjected to a decrease in performance during winter. Other processes, such as activated sludge and aerobic biofilm reactors, are less dependent on temperature, as a result of the higher technological input and mechanization level [8].

Rising Sea levels/Storms

With the onset of rising sea levels and floods (water etc.) as well as during destruction flood events of rivers etc., many water utilities have become threatened by flooding which can have multiple negative consequences. Flooded wastewater facilities have the potential to release untreated waste into the ecosystem, thus causing significant damage to the environment and people alike. If the wastewater facility suffered structural damage it may have to release untreated waste for an extended period of time until the plant can be fixed. Flood damage would be costly wastewater municipalities both in terms of financial loss and in terms of threats to public health. Careful advance planning to prepare for the consequences of sea level rise and flooding is essential [9].

Particularly, the effects of increased flooding and Sea Levels on wastewater are:

- with increased storms comes increased flooding which can be harmful to infrastructure when WWTPs are built in coastal areas or in areas affected by river floods(Figure 4a);
- strong waves during storms can be very damaging to effluent pipes, creating more up-keep needs;
- sea level are expected to rise in some areas by 2050 endangering the location of many plants;
- rising downstream water levels may make pumping effluent a requirement, increasing energy need [10].

Increased frequency and intensity of rainfall is one of the most immediate effects of global warming that is already apparent in stream flow records from the last several decades. The expectation is that more severe storms will produce more severe flooding. This will inevitably result in additional water pollution from a large variety of sources. Chief among these are wastewater treatment, storage, and conveyance systems [11].

Increased tropical storm intensities will have negative effects on water resources (Figure 4b). More intense tropical storms can damage infrastructure, because increased flooding, which can overwhelm water infrastructure, and cause pollutants to directly enter waterways and contaminate water supplies [12].

Impacts on water pollution

According to EPA, for the most part, wastewater treatment plants and combined sewer overflow control programs have been designed on the basis of the historic hydrologic record, taking no account of prospective changes in flow conditions due to climate change. As a result, it is conceivable that water suppliers will face a continually increased influent challenge from sewage overflows, producing high concentrations of *Giardia*, *Cryptosporidium* and coliforms [11].

In the future, wastewater reuse and desalination will possibly become important sources, considering reused and water supply in semiarid and arid regions. An increase in wastewater treatment in both developed and
developing countries is expected in the future, but point-source discharges of nutrients, heavy metals and organic substances are likely to increase in developing countries. In addition, more frequent heavy rainfall events will overload the capacity of sewer systems and water and wastewater treatment plants more often. An increased occurrence of low flows will lead to decreased contaminant dilution capacity, and thus higher pollutant concentrations, including pathogens. In areas with overall decreased runoff (e.g., in many semi-arid areas), water quality deterioration will be even worse [14].

1.2.1.2 Affected processes in a WWTP

The main processes in a WWTP that are affected by the climate change are listed below:

- **Sedimentation**
  - Warm wastewater increases the bacterial reaction rate which reduces the density of settled sludge;
  - Inflow wastewater will be more dense so experiments will need to be done;

- **Biological Aeration of warm wastewater**
  - Increased BOD;
  - Activated sludge aeration systems operating at high temperatures support nitrification;

- **Processing of waste sludge**
  - Waste activated sludge must be thickened for efficient and effective digestion;

- **Stabilization Ponds**
  - Pros: reliable treatment, and minimal operation/maintenance;
  - Cons: land demand, infrastructure, sealed bottoms to prevent groundwater contamination, potential emission of foul odors;

- **Chlorination**[11].

1.2.2 MBRs affected by Climate Change

In biological wastewater treatment (WWT), the removal of organic matter relies on the activity of a mixed community of heterotrophic microorganisms. In order to control the efficiency of the WWT processes, it is important to recognize the variables that regulate microbial hydrolases. The activity of these enzymes in WWT plants is controlled by diverse microbial mechanisms which respond to changes in the variables influencing the system, such as the availability of nutrients, electron acceptor conditions, pH or seasonal temperature.

The adaptation of the hydrolytic activities of the activated sludge microbial community to changes in variables influencing a full-scale MBR system is examined by researchers in three different seasons of the year (spring, summer and autumn). Daily medium internal temperature measured in the sludge of the MBR system, Concentration of total suspended solids (TSS), concentration of volatile suspended solids (VSS), concentration of total nitrogen (tN), total chemical oxygen demand (COD), and total biological oxygen demand at five days (BOD5) were analyzed daily in influent and effluent (permeate) water.

Significant differences (p < 0.1) were found depending on the season. Important fluctuations in the enzyme activities were recorded for all tested hydrolases, particularly during the spring. The highest quantitative variation between seasons was observed for α-glucosidase, which was higher in the spring compared to the summer and autumn [15].

1.2.3 Applied Solutions

Growing evidence indicates that the water sector will not only be affected by climate change, but that it will deliver many of its impacts through floods, droughts, or extreme rainfall events. Water resources will change in both quantity and quality, and water, storm water and wastewater facilities’ infrastructure will face greater risk of damage caused by storms, floods and droughts. The effect of the climate change will manifest from difficulties in operations to disrupted services and increased cost of the water and wastewater services. Governments, urban planners, and water managers must therefore re-examine development processes for municipal water and wastewater services and are adapting strategies to incorporate climate change into infrastructure design, capital investment projects, service provision planning, and operation and maintenance.
Wastewater systems built on historical design parameters, such as max/min flow levels or storm water capacity, will become obsolete and reconstruction rather than rehabilitation may become necessary. With reduced flow in receiving water, meeting the ambient water standards after dilution of wastewater treatment plants’ effluent may become increasingly difficult and can result in a need for increased treatment standards [16].

Adaptive capacity

The degree to which a municipality is able to deal with the impacts of climate change is often referred to as adaptive capacity. According to the Intergovernmental Panel on Climate Change (a global scientific body set up by the World Meteorological Organization and the United Nations Environment Program), Adaptation is defined as “the ability of a system to adjust to climate change (including climate variability and extremes) to moderate potential damages, to take advantage of opportunities, or to cope with the consequences” [17].

Assessment tool

To consider the effects of a facility flooding on the surrounding community, an impact assessment tool was created. Suitable tools were developed for wastewater facilities. The crucial factor that was considered for wastewater facilities was the ratio between average flow rate and design flow rate of the plant. This ratio measures how close to maximum capacity a wastewater treatment facility operates. A facility which operates close to maximum capacity will be less able to handle an increase in inflow which may be caused by a storm or flood than that another facility which does not operate close to maximum capacity. Facilities which have an average flow rate of up to 50% of their design capacities were rated as low impact, facilities with an average flow rate above 50% and up to 70% of their design capacities were rated as medium impact, and facilities with an average flow rate above 70% of their design capacities were rated as high impact [9].

Monitoring of wastewater treatment plants

Over the last decade, continuous and long term monitoring of urban wastewater infrastructure has increasingly been applied due to the availability of reliable and affordable sensors, data communication and data handling capacity. This has resulted in the availability of large data sets, describing the performance of the wastewater infrastructure in long time series. Combining these monitoring data with meteorological data, it is possible to study the impact of anticipated climate changes by identifying periods in time in the data set that resemble weather conditions representative of expected future climatic situations. This ‘data mining’ could result in identifying relevant processes to be taken into account in a model-based analysis of climate change impacts [18]. Wastewater operations monitoring provide changes in volumes and composition of wastewater, brakes and clogs in wastewater collection network, adequacy of existing technology to composition of wastewater and wastewater treatment effluent and sludge [16].

Vulnerability analysis

Water utilities across the country have initiated research efforts to investigate their vulnerability to climate change processes. Such efforts attempt to obtain a better analytical assessment of the possibility that current water resource development and facility plans could be disrupted by near-term (20-50 year) manifestations of climate change processes. This initial focus on vulnerability is a good means of identifying a utility’s priority issues relating to climate change and laying the groundwork for follow-up actions. Two alternative approaches to vulnerability analysis have been articulated: “top-down” and “bottom-up.” Many initial vulnerability analyses have related to water resource and facilities planning. However, direct impacts to water utility facilities from flooding due to more intense rainfall activity or sea level rise are other obvious priorities for such analysis.

Some of these efforts have employed climate models (referred to as GCMs – General Circulation Models) to attempt to build climate change forecasting into the front end of water supply planning. This has been labeled the “top down” approach to vulnerability analysis. The major drawback of this approach lies in the current level of analytical resolution of the GCMs. In contrast, a “bottom-up” approach to vulnerability analysis has also been articulated as a recommended path for utilities to follow in investigating impacts of climate change. The central idea of this approach is that utilities can work with their own water resources planning models to assess the vulnerability of their 20-50 year supply plans to climate change. The “bottom-up” analysis enables a utility to
test the robustness of current plans to upsets from changes in key climate-related variables limited to one or several models and without trying to undertake new climate modeling work [11].

Membrane treatment processes

Many water suppliers in over-constrained settings have also turned to energy-intensive membrane treatment processes to enable desalination of saline water sources and reuse of highly treated wastewater effluent. These processes make it possible to overcome deterioration in the reliability of normal sources of supply by making it possible to meet part of the demand from sources that will be abundant under most climate change scenarios (i.e., yields from water reuse and desalt supply options are drought-resistant). If these technologies can plug a gap, or shore up a vulnerability produced by climate change processes, in a way that enables a broader scope for optimization across the entire portfolio, then they could play a critical role in improving the overall optimization [11]. For optimization purposes, a lab-scale pilot plant which consists of a sequence of four tanks: 1. waste; 2. biological treatment; 3. separation activated sludge membranes; 4. treated waste, with fully automatic operation, has been constructed and tested (the automatic operation of the pilot plant is achieved by means of programmable logic controller - PLC), by Gkotsis et al., [19].

1.3 Climate Change affected by WWT

1.3.1 Associated Problems

The quantity of wastewater collected and treated is increasing in many countries in order to maintain and improve potable water quality, as well for other public health and environmental protection benefits. Concurrently, GHG emissions from wastewater will decrease relative to future increases in wastewater collection and treatment [14].

The study of gaseous emission, climate change and air pollution is committed to physico-chemical identification, inventories, and measurement and assessment methods as well as on quantitative study of the actual anthropogenic sources and its direct contributions. The causes brought on by human activities include:

i. Emissions from wastewater discharges;
ii. Sewage collection and transportation;
iii. Wastewater treatment plants (WWTPs); and
iv. Associated activities.

The level of uncertainty in the wastewater industry’s “carbon profile” is unacceptable in the emerging business environment of carbon pricing, and managerial commitments to “zero carbon emission”. Methane and nitrous oxide emissions in particular have much higher global warming potentials than carbon dioxide [20].

1.3.2 GHG emissions from wastewater treatment

During the wastewater treatment, greenhouse gases (GHG) including carbon dioxide (CO₂) from aerobic (oxidation processes), methane (CH₄) from anaerobic processes and nitrous oxide (N₂O) associated with nitrification/denitrification (NDN) processes, as an intermediate product, can be emitted to the atmosphere. Table 2 displays the expected GHG emissions that occur during the processes in a WWTP.

Table 2: Expected Direct GHG Emissions for WWT Plant Processes [21].

Municipal sewage treatment plants play an important role in the abatement of water pollution, but they also produce a large amount of gaseous emissions to atmosphere. The discharge of large volumes of fugitive gases that contains low levels of chemical constituents may still lead to an excessive contribution to air pollution.
Most centralized wastewater treatment methods consist of combination of biological processes (activated sludge reactors, trickling filters, anaerobic digesters, etc) that promote biodegradation of organic matters by micro-organism and production of anthropogenic CH₄ and N₂O gaseous emissions. Methane (CH₄) production is directly resulting from anaerobic decomposition of the organic matter present in sewers. The methanogenesis or CH₄ production rate depends primarily on the concentration of the degradable organic material in wastewater measured by Biochemical Oxygen Demand (BOD₅) and Chemical Oxygen Demand (COD). The main environmental factors which influence methane production include; retention time, pH, temperature, presence of sulphate reducing bacteria and methanogens [22, 23].

Nitrous Oxide (N₂O) and nitric oxide (NO) production is associated with breakdown of nitrogen components that are common in wastewater, e.g. protein, urea. Biological nutrient removal (BNR) processes have the ability to transform the ammonia and organic nitrogen compounds into nitrogen gas, which can be released to the earth's atmosphere. The two-phase process involves nitrifying bacteria (Nitrosomonas) that oxidize ammonia to create nitrate (aerobic phase), while denitrifying bacteria reduce nitrate, turning it into nitrogen gas, which is then released to the atmosphere (anoxic phase). N₂O and NO can be released during both of these processes; however it is mainly associated with denitrification. Aerobic treatment process produces relatively small emissions, whereas anaerobic processes emission can increase by 50-80% [23, 24].

Carbon Dioxide (CO₂) production is attributed to two main factors; treatment process and (indirectly) to electricity consumption. During anaerobic process the BOD₅ of wastewater is either incorporated into biomass or it is converted to CO₂ and CH₄. A fraction of biomass is further converted to CO₂ and CH₄ via endogenous respiration. Short-cycle or natural sources of atmospheric CO₂ which cycles from plants to animals to humans as part of the natural carbon cycle and food chain do not contribute to global warming. Photosynthesis produced short-cycle CO₂ removes an equal mass of CO₂ from the atmosphere that returns during respiration or wastewater treatment. Digestion processes, either aerobic or anaerobic, also only emit short-cycle CO₂ [23].

The hydrogen sulphide (H₂S) gas evolves from the anaerobic decomposition of organic matter or from the reduction of mineral sulphites and sulphates. H₂S gas mixed with the sewage gases (CH₄ + CO₂) is highly corrosive to sewer pipelines, manholes, concrete junction chambers, mechanical and electrical equipment [22, 23].

Volatile Organic Compounds (VOCs) emission occurs during entire wastewater cycle. A significant fraction of VOCs is released to atmosphere by gas-liquid mass transfer. VOCs production during wastewater transportation in sewers occurs during turbulent flow and air exchange between ambient atmosphere and wastewater. The transfer rate of emission is affected by physicochemical properties of chemicals, fluid and flow characteristics. There is a growing concern that several VOCs that are present in wastewaters, especially industrial effluents, find their way to the atmosphere. In particular VOCs such as benzene, chloroform, ethyl benzene, toluene, m-xylene and o-xylene are found in refinery and petrochemical wastewaters in significant amounts as well as in many municipal wastewaters [23, 25, 26].

1.3.3 Climate Change affected by MBRs

The major fugitive GHG emissions are sourced from the anoxic/aerobic zones in the MBR systems (especially of decentralized systems). When the MBR is coupled with an upstream primary holding tank, the susceptibility to various shock loads is enhanced owing to its buffering capacity. The membrane reactor (MBR) system is relatively robust to hydraulic shock loads with tolerance up to 1.5 times of the design dry weather daily flow. However, the stability of nitrification process in MBR is significantly affected when the total nitrogen load in the influent increased by 30% while maintaining the constant inlet wastewater flow rate. By a mass balance approach to estimate the fugitive GHG emissions is concluded that electrical energy consumption data alone could substantially underestimate the overall GHG footprints for the MBR systems [27].

It was found that the aerobic tank did not emit any fugitive gases, apart from a very small amount of CH₄ released after surface watering. This small amount of CH₄ may have been released from sludge deposited via water spray from the anoxic tank. The anoxic tank emitted highly variable amounts of both CH₄ and N₂O during all three operational conditions, with the highest level of CH₄ (53 g CO₂-e/m²/d) being emitted after a 2-hour
site shutdown period, whilst the most N₂O (17 g CO₂-e/m²/d) was emitted when the MBR system was working under normal conditions [28].

1.3.4 Applied Solutions

1.3.4.1 General

As climate change is a major concern, alternatives should reduce greenhouse gas emissions, making anaerobic treatment a more attractive component of novel approaches to treatment processes.

Vulnerability and climate assessment

The definition of assessment framework, proposed by Listowski et al. in 2011 [23] for gaseous emissions from urban wastewater system (Figure 6), appears necessary to the development of future adaptation strategies and knowledge to manage emissions from wastewater cycle. It should be developed to interact with the adaptive responses that could address emission sources, infrastructure, the pathways for gaseous emissions and its concentrations, mitigation capabilities and technologies. The main tasks in assessment framework incorporate several areas including:

- Understanding emission generation processes (spatial, temporal, physical, bio-chemical) with the key motivation issues including the pathways for gaseous emissions and concentrations;
- Identification of appropriate and reliable parameters as a basis for the adaptation of the strongly variable combined wastewater flow to the actual treatment capacity;
- Establishment of credible methods of obtaining data and information from defined emission sources;
- Quantification and predictions of gaseous emissions. Amongst the broad diversity of wastewater sector the analysis of gaseous emissions could be assessed in two essential emission categories:
  - Direct emission related to wastewater sources and activities that promote fugitive gaseous emission related to physical and biochemical processes that are characteristic to wastewater and its by-products during the wastewater cycle;
  - Indirect emission - energy use associated with the wastewater transportation, pumping, various treatment processes, effluent disposal, residuals management, etc.

Figure 6: GHG emission assessment framework from wastewater [23].

The main factor in this regard is the use of biological wastewater treatment, aerobic or anaerobic treatment technology, sludge processing and also the electricity used. While assessment of emission related to energy consumption (CO₂ equivalent) is relatively straightforward, quantifying direct fugitive emissions (“fugitive” emissions of nitrous oxide and methane from WWTP operations since both of these gases are major greenhouse contributors) from wastewater systems is an area of uncertainty for the industry, with less developed and less reliable methodologies. The diffused emissions include substances such as: CH₄, CO₂, VOCs, NOₓ, CO,
Mercury, Cadmium and Lead, hydrogen sulphide \((H_2S)\), ammonia \((NH_3)\), and sulphur dioxide \((SO_2)\), which have adverse affect on air quality, environment and public health [23].

**Methane as a fuel**

The methane emission related to the anaerobic digestion of primary and secondary sludge counts for about three quarters with respect to the WWTPs overall methane emission and causes a slightly larger greenhouse gas footprint than the carbon dioxide emission that is avoided by using the resulting biogas for energy generation. Methane emissions can be significantly reduced by better handling of the ventilation air of sludge handling facilities; one way to valorize the residual methane that is produced in the buffer tank is to use the ventilation air from the buffer tank as combustion air in the gas engines of the cogeneration plant. The methane concentration in the ventilation air could of course be increased by using less fresh air for ventilation. This would result in less diluted methane streams, but then the ventilation system should be adapted to handle methane concentrations that exceed the lower explosive limit of methane in air, which is 4.4% [29].

Recovering the energy to provide heat and electricity for WWTPs process can offset significant fossil fuel-related GHG emissions. In general, intuitively sustainable practices for biosolids (energy recovery and recycling nutrients and organic matter) reduce GHG emissions. Besides, the methane that is emitted to the atmosphere not only contributes to the greenhouse gas footprint of a WWTP, it also implies a waste of energy since the methane emitted from the unit processes that are related to the anaerobic digestion (7-2% of the produced methane) could potentially have been used as a fuel for the cogeneration plant. Although biogas production from waste sludge may be a sustainable technology from an energy point of view, it has in this case no benefits over fossil fuel-derived energy regarding greenhouse gas emissions. Nonetheless it should be emphasized that the emission of methane is not intrinsic for anaerobic digestion, but that a better design and good housekeeping may lead to a drastic mitigation of the emission [29].

1.3.4.2 MBRs

Interestingly, the lowest emissions of both \(CH_4\) and \(N_2O\) were measured to be over the anoxic tank after cleaning and surface watering was performed. This reduction may have been due to the sprayed and deposited water forming a microlayer membrane or a thicker film as a protective barrier over the sewage surface, which may have prevented a large proportion of gases from being released into the atmosphere. During all operational conditions, \(CO_2\) emissions were also found to be released from both the aerobic and anoxic sections of the MBR system. However, this \(CO_2\) is widely regarded as being a short-term biogenic gas readily produced by the breakdown of organic matter. As it is not generated by fossil fuel burning and does not measurably contribute to the greenhouse effect, it is not included in the total GHG emissions footprint [28].

In the absence of any data, it could be assumed that \(N_2O\) and \(CH_4\) emissions would not be significant as the system remains aerobic. This means that \(CH_4\) should not form in significant amounts, and that denitrification is unlikely to occur so limited amounts of \(N_2O\) should form [30].

1.4 Conclusions

It is estimated that Climate change has a dual action on wastewater treatment plants. The processes occurring in a WWTP are subsequently affected by climate change; more extreme weather events and earlier snowmelt runoff will lead to more untreated sewer overflows, increased flooding, etc. Most wastewater infrastructure consists of transmission facilities, treatment facilities, and discharge bodies. The impacts to the wastewater infrastructure can be categorized as:

- Impacts indirectly associated with climate change such as the decrease in water usage associate with water conservation; and
- Impacts directly associated with climate change on the infrastructure.

The limitation of climate changes’ effects on WWT processes can be achieved by applying an impact assessment tool, by monitoring of wastewater treatment plants and by using vulnerability as a good means of identifying a utility’s priority issues relating to climate change.

In the other hand, we have the WWT contribution to climate change itself, as during the wastewater treatment, greenhouse gases (GHG) including carbon dioxide (\(CO_2\)) from aerobic (oxidation processes),
methane (CH₄) from anaerobic processes and nitrous oxide (N₂O) associated with nitrification/denitrification processes, as an intermediate product, can be emitted to the atmosphere.

The development of future adaptation strategies and knowledge to manage emissions from wastewater cycle appears necessary and the Vulnerability climate assessment should be developed to interact with the adaptive responses that could address emission sources. Furthermore, recovering the energy to provide heat and electricity for WWTPs process by using the resulting biogas from the anaerobic digestion of sludge can offset significant fossil fuel-related GHG emissions (CH₄ etc.)

During MBRs operation, the major GHG emissions (mainly N₂O and CH₄) are sourced from the anoxic/aerobic zones of the MBR systems (especially of decentralized/small systems); however, it could be assumed that N₂O and CH₄ emissions would not be significant, as the system remains aerobic. In the other hand, the microbial communities developed in MBR-based treatments are exposed to completely different conditions depending on the season of the year (spring, summer and autumn).

Acknowledgments

The financial support through the co - Financed by the European Union and the Greek State Program EPAN-II (OPC-II)/ESPA (NSRF): 'SYNERGASIA II', Project (FOUL-MEM) - "New processes for fouling control in membrane bioreactors (11SYN-8-1084), is gratefully appreciated.
